Rhodococcus equi is a facultative intracellular pathogen, which cause severe pyogranulomatous pneumonia in foals and tuberculosis-like lesions in humans. Its ability to form biofilm was described in strains isolated from chronic diseases associated to treatment failures in humans. This study aimed to verify the biofilm formation by 113 *R. equi* isolated from equine samples (clinical and fecal) using two different methods (biofilm-culturing with and without additional glucose and epifluorescence microscopy). We also aimed to determine the efficacy of azithromycin, clarithromycin and erythromycin on *R. equi* in established biofilm. We found 80.5% (26/41) and 63% (58/72) biofilm-positive isolates, in fecal and clinical samples, respectively. The additional glucose increased the biofilm formation by *R. equi* fecal samples, but not by clinical samples. The antimicrobials tested herein were not able to eradicate *R. equi* in biofilm even at higher concentrations. This is the first study showing the biofilm formation by *R. equi* isolated from equine samples. Our findings indicate that *R. equi* biofilm-producers may be more resistant to the antimicrobials evaluated. Further studies are warranted to test this hypothesis.

INDEX TERMS: Antimicrobial resistance, biofilm, DAPI, macrolides, *Rhodococcus equi*.

RESUMO.- [Formação de biofilme por *Rhodococcus equi* e possível associação com resistência a macrolídeos.]

Rhodococcus equi é um patógeno intracelular facultativo, o qual causa pneumonia piogranulosa severa em potros e lesões semelhantes à tuberculose em humanos. A sua capacidade de formar biofilme foi descrita em cepas humanas, isoladas a partir de doenças crônicas associadas a falhas

de tratamento. Este estudo teve como objetivo verificar a formação de biofilme por 113 cepas de *R. equi*, isoladas a partir de amostras de equinos (clínicas e fecais), utilizando-se dois diferentes métodos (biofilme em cultura - com e sem adição de glicose - e microscopia de epifluorescência). Além disso, buscou-se determinar a eficácia da azitromicina, claritromicina e eritromicina sobre biofilme consolidado de *R. equi*. Verificou-se 80,5% (26/41) e 63% dos isolados (58/72) positivos para formação de biofilme, em amostras fecais e clínicas, respectivamente. A adição de glicose aumentou a formação de biofilme em amostras fecais, mas não em amostras clínicas. Os antimicrobianos aqui testados não foram capazes de erradicar *R. equi* em biofilme consolidado, mesmo em concentrações elevadas. Este é o primeiro estudo a demonstrar a formação de biofilme por cepas de *R. equi* isoladas a partir de amostras de equinos. Os resultados indicam que os isolados de *R. equi* produtores de biofilme podem ser mais resistentes aos antimicrobianos avaliados. Estudos adicionais são necessários para testar essa hipótese.

INTRODUCTION

Rhodococcus equi is a facultative intracellular and telluric pathogen (Prescott 2004). It is also the etiologic agent of equine rhodococcosis, a disease that typically affects 3-week to 6-month-old foals (Giguère & Prescott 1997). This bacterium has a worldwide distribution and is frequently widespread in the environment, such as horse-breeding farms (Takai 1997) and public areas, including sand areas in parks (Takai et al. 1996, Fernandes et al. 2013). Furthermore, *R. equi* was described as a causative agent of opportunistic infections, especially in immunocompromised humans (Arlozzi et al. 1996). In these patients, the clinical manifestations are similar to those of pulmonary tuberculosis, with prominent fatality rates (Muscatello et al. 2007). Moreover, reports of rhodococcosis infection have increased in immunocompetent patients (Von Bargen & Haas 2009).

The discovery of virulence plasmids in *R. equi* allowed its classification as virulent, intermediately virulent and avirulent. Virulent isolates have a large plasmid that encodes a cluster of genes encoding proteins associated with virulence, including the virulence-associated protein A (VapA) (Takai et al. 1991). Virtually, all isolates from affected foals contain the VapA, considered a key factor in the rhodococcosis occurrence in these animals (Takai et al. 1996). On the other hand, several points associated with the survival and proliferation of *R. equi* in the environment, as well as in the foal's lungs, still remain unknown (Muscatello et al. 2006). After *R. equi* genomic sequencing some putative virulence factors were described, including genes potentially responsible for extracellular polysaccharides (EPS) synthesis (Letek et al. 2010). Bacteria surrounded by EPS material are known as biofilm-producers, an important convergent survival strategy among the microorganisms (Donlan & Costerton 2002). Biofilm is considered a phase of bacterial development in which the bacteria change from the planktonic form to the sessile life (O'Toole et al. 2000). The biofilm-forming bacteria can tolerate antimicrobial concentrations up to 1,000 times more than the same bacterial species in their planktonic form (Costerton et al. 1999, Mah & O'Toole 2001).

Diseases associated with biofilms require novel methods for their prevention and treatment. In this respect, the ability to form biofilm has been evaluated in *R. equi* isolates from humans showing bacteremia after prolonged treatment (Akhrass et al. 2012, Remuzgo-Martínez et al. 2013). The currently therapy of equine rhodococcosis consist of macrolide associated to rifampin, for which there is emergence of resistance (Giguère et al. 2010). Additionally, there is no clear and straightforward antimicrobial protocol that would indicate an adequate treatment for animals infected by the resistant strains (Cisek et al. 2014). Due the above described, this study aimed to verify the biofilm formation by 113 *R. equi* isolates from equine samples (clinical and fecal) using three different approaches. We also aimed to determine the efficacy of three macrolide antibiotics on *R. equi* in established biofilm.

MATERIALS AND METHODS

Bacterial samples

A total of 113 equine *Rhodococcus equi* isolates from clinical ($n=41$) and fecal ($n=72$) samples were used in this study. The clinical samples were recovered from *post-mortem* pulmonary and extra pulmonary lesions in horses subsequent to antimicrobial treatment, and the fecal samples were recovered from healthy mares. These samples were obtained from ten horse-breeding farms in the south of Brazil from 1991 to 2009. All samples were characterized as *R. equi* by morpho-dyeing and biochemical testing according to Quinn et al. (1994) and the identification was confirmed genotypically by Monego et al. (2009). *R. equi* isolates were lyophilized and stored at -20°C until the tests were performed.

Biofilm development

Biofilm-culturing (BC) assay. This method was chosen because it is considered the gold-standard method for biofilm detection (Mathur et al. 2006). The quantitative determination of biofilm formation was performed by the spectrophotometric method, which measures the total biofilm biomass, including bacterial cells and EPS matrix. This assay was performed as described previously (Merino et al. 2009) with minor modifications. Briefly, $5\mu\text{L}$ [$\approx 10^8$ colony forming units (CFU)/mL] of a culture of *R. equi* grown overnight in tryptone soya broth (TSB) medium (Himedia® Laboratories) at 37°C were inoculated into 96-wells microtiter plates (Nunclon® Delta) containing $195\mu\text{L}$ of TSB. After 24 h of incubation at 37°C , in static and aerobic conditions, the microtiter plates were washed three times with $200\mu\text{L}$ of sterile water, dried in an inverted position, and stained with $100\mu\text{L}$ of 0.25% crystal violet for 5 min at room temperature. Following the microtiter plates were rinsed again three times with sterile water and dried. Later, the dye was dissolved in $200\mu\text{L}$ of ethanol-acetone (80:20), and the absorbance was measured in an ELISA microtiter-plate reader (SpectraMax®, Molecular Devices) at 570nm-wavelength. All assays were performed in triplicate and repeated three times. Uninoculated TSB medium was used as a negative control. To ensure the quality of the tests, a reference strain of *Staphylococcus aureus* ATCC 25923 was used as positive control for biofilm formation (Marques et al. 2007). Absorbance values greater than the negative control were considered positive. The arithmetic mean of the triplicates was calculated.

Biofilm-culturing with additional glucose (BCG) assay. Although *R. equi* is not known to use sugars, fermentation pathways involving the glucose metabolism have recently been proposed according to the available genome (Letek et al. 2010). Given the importance of glucose as substrate for biofilm-producers (Agarwal & Jain, 2013) we evaluated its influence on biofilm formation by *R. equi*. The method above was employed with additional 0.25% glucose in the TSB medium and all *R. equi* isolates were retested.

Epifluorescence microscopy (EM) assay. *R. equi* isolates were cultured in TSB medium at 37°C during 24 h in aerobic conditions. An inoculum ($200\mu\text{L}$) corresponding to $\approx 10^8$ CFU/mL of each *R. equi* cultures grown overnight under static conditions was distributed in a sterile petri plate (50mm x 10mm) containing a sterile coverslip (18mm x 18mm) and 3.0mL of TSB. All plates were incubated under the same conditions as described above. Next, the coverslips were then heat-fixed and stained with $10\mu\text{L}$ of 4,6-diamino-2-phenylindole (DAPI; Sigma®) (2mg/mL) and attached to slides. The biofilm formation on the coverslips was observed with an epifluorescence microscope at 100x lens (395nm of absorption and 440nm of emission). Biofilm-forming bacteria were observed in conjunction with the EPS matrix. Bacteria were

considered biofilm-negative when they presented no EPS matrix around the stained cells. This technique was adapted from Feazel et al. (2009).

Antimicrobial activity

Planktonic antimicrobial susceptibility testing. This test was performed to calculate the antimicrobial concentration to be used in the antimicrobial tests with *R. equi* established biofilm. Eight *R. equi* isolates (from clinical and fecal samples), positive in all biofilm formation tests described above (selection criteria), were selected to carry out the antimicrobial susceptibility testing. The minimum inhibitory concentration (MIC) tests were performed in Müller-Hinton broth (MHB) medium (Himedia® Laboratories) using the microdilution method in accordance with the guidelines of the Clinical and Laboratory Standards Institute (CLSI 2013). All microorganisms were cultivated in MHB for 24 h at 37°C. For each microorganism, an inoculum suspension was prepared in 0.9% saline, adjusted to the turbidity of 0.5 on the McFarland' scale, and absorbance readings were performed in a spectrophotometer at 600 nm-wavelength. These suspensions were diluted in MHB to approximately 1×10^5 CFU/mL. The antimicrobials tested were azithromycin (AZT), clarithromycin (CLAR) and erythromycin (ERY), macrolides commonly used in the treatment of equine rhodococcosis. The antibiotic concentrations tested were: 0.0625, 0.125, 0.25, 0.5, 1, 2, 4, 8, 16, 32, 64, and 128 µg/mL. The reference strain *Staphylococcus aureus* ATCC 29213 was used for assay validation. *R. equi* ATCC 33701, known to be susceptible to azithromycin, clarithromycin and erythromycin, was also used as control (Giguère et al. 2010). The MIC was defined as the lowest concentration of antimicrobials that inhibited the visible growth ($\geq 99\%$) of *R. equi* after incubation. *R. equi* isolates were categorized as susceptible (≤ 2 µg/mL - azithromycin and clarithromycin, and ≤ 0.5 µg/mL - erythromycin) or resistant (≥ 8 µg/mL - azithromycin, clarithromycin and erythromycin) in accordance with CLSI (2008 and 2009). Additionally, isolates with MIC values between the aforementioned concentrations were categorized as intermediate susceptibility.

Biofilm antimicrobial susceptibility testing. This test was performed verify the effect of the same antimicrobials used in the test described in 2.3.1 item against the same *R. equi* isolates, but in established biofilms. This technique was adapted from Cerca et al. (2005). Briefly, overnight *R. equi* cultures grown under static conditions were inoculated into TSB medium in 1:100 dilution in

24-well cell culture plates (Falcon). These plates were incubated at 37°C during 24h. Afterward, all wells were rinsed three times with phosphate-buffered saline (PBS), without disturbing the adherent film, and 1mL of the solution containing antimicrobials (8µg/mL) diluted in TSB medium or only TSB medium (control) was added to each well. The plates were incubated at 37°C for 24h. The solutions were aspirated and all wells were rinsed three times with PBS and the biofilm were disrupted with a solution of Triton X-100 1% in PBS for 20 min. The viable cells were determined by performing 10-fold serial dilutions of this suspension and plating 100µL of the dilutions in triplicate on tryptone soya agar (TSA) plates that were then incubated for 24h at 37°C. This experiment was repeated two times, with individual samples evaluated in triplicate.

Statistical analysis

The Kruskal-Wallis test was used to calculate the difference in the frequency of biofilm formation among the methods. The correlation between the assays were performed by Spearman correlation analysis. The difference in the CFU counts among the groups was compared by one-way Analysis of Variance (ANOVA) followed by the Tukey's test. The minimum significance level considered was $P < 0.05$. The data were analyzed by SAS statistical software.

RESULTS

Detection of biofilm formation

The results may be verified in Table 1, briefly, biofilm formation was observed in 46% (52/113), 56% (63/113)

Table 1. Total number and relative frequency of *Rhodococcus equi* biofilm-producers according the sample source and assay employed

Samples source	Number of biofilm-producers isolates (%)			
	Biofilm-culturing	Biofilm-culturing + Glucose	Epifluorescence microscopy	Cumulative*
Clinical	19/41 (46%) ^a	17/41 (41%) ^a	16/41 (39%) ^a	26/41 (63%)
Fecal	33/72 (46%) ^a	46/72 (63%) ^b	46/72 (63%) ^b	58/72 (80.5%)
Total	52/113 (46%)	63/113 (56%)	62/113 (55%)	84/113 (74%)

* It was classified as biofilm-producer the isolate positive in at least one assay performed.

^{a,b} Within a line and column, values with different superscripts are significantly ($P < 0.05$) different regarding the sample source versus the assay employed and assay according the sample source, respectively.

Fig.1. Biofilm formation by *Rhodococcus equi* isolates. The bacteria were grown on a glass slide during 24 h, stained with DAPI and examined with an epifluorescence microscopy (100x). (a) Aggregate of *R. equi* cells without EPS matrix. (b) Aggregate of *R. equi* cells surrounded by EPS matrix (clouding effect surrounding the bacteria due the biofilm formation). Scale bar = 20µm.

and 55% (62/113) of *R. equi* isolates using BC, BCG and EM assay, respectively. There is no statistically significant difference between clinical and fecal samples regarding the biofilm formation, however, we found significant increase in fecal *R. equi* isolates when glucose was added (Table 1). Biofilm positive and negative *R. equi* cells accessed by EM are demonstrated in Figure 1a and 1b, respectively.

Correspondence among assays

The biofilm-positive *Rhodococcus equi* in at least one of the tests performed were considered biofilm-producer. Therefore, biofilm formation was verified in 74.3% (84/113) of *R. equi* isolates analyzed, with 63.4% (26/41) and 80.5% (58/72) of clinical and fecal isolates, respectively. Eight clinical *R. equi* isolates recovered as biofilm-positive by BC became biofilm-negative in BCG, and six isolates recovered as biofilm-negative by BC had a biofilm-positive phenotype in BCG. On the other hand, in fecal isolates, 18 biofilm-negative strains in BC were observed as biofilm-positive in BCG. All biofilm-positive fecal isolates in BC remained biofilm-positive in BCG.

For clinical isolates, a correlation index of 0.56 was observed among BC, BCG and EM ($P=0.0001$) using the Spearman analysis. On the other hand, fecal *R. equi* isolates showed an increase in the biofilm-formation frequency when used BCG and EM tests, which had the same sensibility to detect biofilm formation, showing a strong correlation index of 0.52 ($P = 0.0001$).

Antimicrobial activity

Antimicrobial susceptibility testing of planktonic *R. equi* suspensions. We evaluated the *in vitro* antimicrobial susceptibility of eight planktonic suspensions of *R. equi* (four from clinical samples and four from fecal samples) to AZT, CLAR and ERY. All isolates analyzed were susceptible to AZT and CLAR. To ERY, four isolates showed intermediate susceptibility and four were susceptible. The results may be observed in Table 2.

Antimicrobial susceptibility testing of *R. equi* in established biofilms. We used the antimicrobials at concentrations at least 4 times their respective MICs to evaluate their effects on established biofilms. At 24 h incubation

Table 2. Minimal inhibitory concentration of azithromycin, clarithromycin and erythromycin against clinical and fecal *Rhodococcus equi* isolates

Strain (n = 8)	MIC (µg/mL)

S: ≤ 2 µg/mL (AZM and CLR) and ≤ 0.5 µg/mL (ERY); R: ≥ 8 µg/mL (AZM, CLR and ERY), IS: MIC values between the concentrations mentioned (CLSI, 2008 and 2009).

there was significant ($P<0.05$) decrease in *R. equi* concentration in presence of AZT, CLAR and ERY. We observed a nearly 3-log order decrease in *R. equi* concentration relative to control levels (untreated cells) (Table 3). However, none of the antimicrobials used were able to eradicate *R. equi* in established biofilms (Table 3).

DISCUSSION

The biofilm formation by bacterial pathogens of veterinary importance has received relatively little attention (Jacques et al. 2010). According to Kaplan (2010) the microorganisms detached from biofilms have an important role in the bacterial dissemination of environmental reservoirs to human or animal, as well as the microorganism transmission among hosts. It is well known that biofilm provides resistance to antimicrobials and play an important virulence factor in chronic bacterial infections in animals, such as endometritis in horses (Ferris et al. 2014). The ability of *Rhodococcus equi* to form biofilm can be highly favorable for its survival in the environment as well as in the host. This is the first study evaluating the biofilm formation by *R. equi* with significant number of isolates.

Several conditions can influence the biofilm formation/detection, such as the method employed, nutritional requirements and metabolic pathways (e.g. glucose, iron

and phosphate concentration) (Jacques et al. 2010). Considering this, we aimed verify the *R. equi* biofilm formation using two different methods and one nutritional variable. For isolates from the same source, all approaches showed high concordance ($P=0.0001$). Thus we classified as biofilm-producer the *R. equi* isolate positive in at least one of the tests performed. Although some isolates were found biofilm-positive in one method and negative in another, this was not unexpected. Similar findings was observed by Knobloch et al. (2002) studying biofilm formation by clinical and commensal *Staphylococcus aureus*.

Glucose seems as an important substrate required for biofilm-formation by fecal-isolates of *R. equi* (Table 1). Studies involving several microorganisms also observed an increase in the ability to form biofilm when used glucose medium supplemented (reviewed by Stepanovic et al. 2007). In contrast, the presence of glucose did not influence the biofilm formation by clinical isolates (Table 1). We believe that different regulatory mechanisms or conditions could be active in biofilm expression between pathogenic and environmental *R. equi*. According to Coelho et al. (2008) the biofilm formation is complex and probably multifactorial, with different substrates and expression autoinducers, especially among isolates from different source.

Among the fecal-isolates of *R. equi*, 80.5% (58/72) were classified as biofilm-producers. The protection ensured by the EPS matrix during stress conditions, including exposition to UV radiation (Espeland et al. 2001) and metal toxicity (Teitzel & Parsek 2003) may be highly advantageous during the saprophytic life of *R. equi*. In this way, Tripathi et al. (2012) showed a mechanism by which the virulence plasmid can move among *R. equi* in the soil. These authors highlight a possible relationship between conjugation and biofilm formation by environmental *R. equi*.

We found 63% (26/41) of clinical-isolates of *R. equi* as biofilm-producers. Usually, bacterial biofilms are associated with prolonged-treatment infections (Kulka et al. 2012), as well as with its recurrence or persistence (Hall-Stoodley et al. 2004). In general, *R. equi* infection has a long-term antimicrobial therapy, around 4-9 weeks, and, besides, these infections become chronic (Prescott 2004). To the best of our knowledge, there are three studies regarding *R. equi* biofilm formation that together evaluated only ten isolates, six clinical (associated to chronic infection in humans) (Akhrass et al. 2012, Remuzgo-Martínez et al. 2013) and four from soil (Mart'yanov et al. 2014). Akhrass et al. (2012) found three strains positive for biofilm formation, while Remuzgo-Martínez et al. (2013) verified only one.

None isolate analyzed here showed resistant profile to antimicrobials (ATM) tested, as presented in Table 2. To access the susceptibility of *R. equi* in established biofilms it was used 8µg/mL of each ATM, 8 to 64xMIC verified for AZT, 32 to 128xMIC for CLAR and 4 to 8xMIC for ERY. A previous study demonstrated that the average of 4 to 8 times the MIC could eradicate biofilm of Gram-positive bacteria (Raja et al. 2011). In the present study, *R. equi* in established biofilms were recovered even after exposure to high ATM concentrations, however, CFU amount reduction was

statically significant (Table 3). Two studies concerning antimicrobial susceptibility of clinical and environmental *R. equi* producing biofilm were performed by Akhrass et al. (2012) and Mart'yanov et al. (2014). The first study found *R. equi* biofilm reduced completely or partially by antimicrobial solutions. Mart'yanov et al. (2014) found a unexpected pattern, *R. equi* biofilm persistence was observed in the treatments with high AZT concentration (15 to 50µg/mL), while at 8µg/mL the planktonic and biofilm growth were similar.

In the present study, we observed a nearly 3-log order decrease in *R. equi* concentration relative to control levels (untreated cells) (Table 3). Similar results were verified by Ojha et al. (2008) with *Mycobacterium tuberculosis* biofilm after rifampicin (50µg/mL) treatment. Although the reduction have been expressive, these authors indicate that subpopulation of cells surviving this treatment were able to replicate following 7 day of exposure. Even exopolysaccharide matrix does not form an impenetrable barrier to the diffusion of antimicrobial agents (Mah & O'Toole 2001), the observation of tolerant subpopulation may mean an important way of ATMs resistance.

Oggioni et al. (2006) observed that cells from biofilm-producing pneumococcal are more effective in inducing pneumonia than the planktonic cells. In addition, microorganisms growing on EPS matrix are able to resist to the host defenses, i.e., by impairing the phagocytic activity of neutrophils (Yamanaka et al. 2009) - and act as reservoirs for antibiotic resistance genes (Jacques et al. 2010). The influence of biofilm in *R. equi* pneumonia, especially in the cases unresponsive to treatment, may require some special attention.

CONCLUSIONS

Both clinical and fecal *Rhodococcus equi* isolates are able to form biofilm according the methods used. Those may represent a quick and reliable methodology to study *R. equi* biofilm.

Glucose addiction seems to increase the ability of fecal isolates to produce biofilms.

None antimicrobials tested was able to eradicate *R. equi* in biofilm, even at high concentrations.

Our findings indicate that *R. equi* biofilm-producers may be more resistant to the antimicrobials evaluated. Further studies are warranted to test this hypothesis.
