Tropical grasses have an important role in forage-based cattle production systems. To guarantee production, it is necessary to understand factors that allow plant growth, as well as photosynthesis. Under grazing, the amount of residual leaf area in post-grazing or plant organic reserves also drives the growth. Thus, gaseous exchange responses in forages are essential for understanding forage production processes, aiming for maximum biological efficiency. The objective of this study was to evaluate foliar photosynthesis and water use efficiency in Quênia (\textit{Panicum maximum} BRS Quênia). The pastures were submitted to intermittent grazing (95\% of light interception) with two grazing intensities defined by post-grazing height: high and low (20 and 35 cm). The experiment was carried out at Embrapa Agrossilvipastoril, Sinop/MT, from March/15 to Feb/16, following a randomized complete block design, with three replications. Data was analyzed using the method of mixed templates, with special structure in the parametric covariance matrix, through the MIXED procedure of SAS statistical software. To choose covariance matrix, the Akaike information was used. Three seasons are evaluated (autumn, spring, and summer), using three leaves (younger fully expanded per tiller) per plot, immediately before grazing. Measurements were performed using the portable infrared gas exchange analyzer (LCi-SD, ADC BioScientific Ltd., Hoddesdon, England). The light intensity was kept constant at 2000 \( \mu \text{mol photons m}^{-2} \text{s}^{-1} \), and readings were taken between 08:30 and 11:00 AM. There is no grazing intensity effect (\( P>0.05 \)) on leaf photosynthesis (27.76 \( \mu \text{mol C}_2 \text{O}_2 \text{ m}^{-2} \text{s}^{-1} \)) and water use efficiency (5.65 \( \mu \text{mol C}_2 \text{O}_2 \text{ mol H}_2\text{O m}^{-2} \text{s}^{-1} \)). Leaf photosynthesis rate and water use efficiency showed grazing intensity x seasons interaction (\( P=0.0317 \) and \( P=0.0215 \), respectively). Despite managed under high or low grazing intensity, grass physiological responses were strongly influenced by climatic conditions, mainly due to variations in water availability that occurred during experimental period. The highest values of leaf photosynthesis (34.09 \( \mu \text{mol C}_2 \text{O}_2 \text{ m}^{-2} \text{s}^{-1} \)) and water use efficiency (4.13 \( \mu \text{mol C}_2 \text{O}_2 \text{ mol H}_2\text{O m}^{-2} \text{s}^{-1} \)) were recorded in spring, a season with greater values of radiation and precipitation. After mid-December, rainfall was enough to guarantee water deficit absence. Quênia guineagrass under intermittent grazing, using 95\% of light interception, can have the post-graze define between 35 and 20 cm of height.

**Keywords:** grazing intensity, grazing management, light interception, tropical grass

Acknowledgments: Unipasto and Embrapa for funding this project.
