ABSTRACT: The aim in the present study was to evaluate the growth of Coffea canephora cv. ‘Conilon BRS Ouro Preto’ seedlings in different tube volumes. The experiment was performed at Embrapa Rondônia plant nursery in Ouro Preto do Oeste, Rondônia, Brazil, from July to November 2013. The treatments consisted of five tube volumes (50, 100, 170, 280 and 400 cm³) plus one control composed by polyethylene bags (11 cm width x 20 cm height) with capacity of 770 cm³. The experimental design was a randomized complete block design with 15 replicates, formed by 15 clones that compose the Conilon ‘BRS Ouro Preto’ cultivar. The tube volume of 280 cm³ provide the best vegetative performance of seedlings, similarly to volume of 400 cm³, thus, the use of larger tubes would not justify. Tubes of 50, 100 and 170 cm³ produce seedlings with physiological quality similar to the control until 130 days after staking, but may limit the development of seedlings in a longer period.

Index terms: Vegetative propagation, cuttings, Conilon, BRS Ouro Preto.

1 INTRODUCTION

The vegetative propagation of Coffea canephora Pierre ex A. Froehner is one of the technologies that favored the increasing crop productivity in the recent decades. Based on this propagation method, it is possible to maintain the genetic characteristics of the matrix plant, guaranteeing crop homogeneity in terms of productivity, yield precocity and grains quality, and obtaining larger grains and maturation uniformity, besides allowing the harvesting scheduling using clones with differentiated maturation cycle (AMARAL et al., 2007; CONTARATO et al., 2010; PARTELLI et al., 2006b). Clonal crops also facilitate the realization of cultural practices, especially when planted in the ‘in line clone’ system (ESPINULA et al., 2015).

The vegetative propagation by cuttings is a simple technique with high setting rates of seedlings (ANDRADE JÚNIOR et al., 2013), being consolidated as the most used propagation method in the commercial production of C. canephora seedlings (ALMEIDA et al., 2011; PARTELLI et al., 2006b). However, there is little progress in relation to the used containers and substrates.

For commercial production of seedlings, polyethylene bags and a mixture of soil and cow dung supplemented with chemical fertilizers (DIAS; MELO, 2009) are usually used. Such way of propagation has high costs with transport and cultural practices, provides propagation of soil pathogens, especially nematodes, and degrades the environment due to large soil movement (VILLAIN et al., 2010).

In contrast, the use of tubes allows forming seedlings in organic substrates, with greater control of nutrition, easiness of management in the nursery, transport and rapid planting (BRAUN et al., 2007; LISBOA et al., 2012). Furthermore,
the twisting of main roots does not occur in these containers, since they are carried vertically through striations present on the inner walls of the container until the hole in the lower base where the pruning of roots occurs in contact with light and oxygen (AMARAL et al., 2007).

Currently, there are several studies related to the development of coffee seedlings by seed in tubes using commercial substrates (DARDENGO et al., 2013; HENRIQUE et al., 2011; MARANA; MIGLIORANZA; FONSECA, 2008; SILVA et al., 2010; VALLONE et al., 2010). However, for clonal seedlings, few scientific articles descript this method.

Several seedling characteristics are influenced by the container size, such as root and shoot growth, and may affect the percentage of survival in the field and crop productivity (LIMA et al., 2006; VALLONE et al., 2009, 2010). Thus, to optimize the volume of containers in the seedling propagation is essential because larger containers can result in unnecessary labor costs, excessive demand for substrates and transportation, besides occupying a larger area in the nursery, raising production costs (AMARAL et al., 2007; CORREIA et al., 2013; DIAS; MELO, 2009).

In this context, the aim in the present study was to evaluate the growth of Coffea canephora cv. ‘Conilon BRS Ouro Preto’ seedlings in different tube volumes.

2 MATERIAL AND METHODS

The experiment was installed in the experimental field of Embrapa Rondônia, in the municipality of Ouro Preto do Oeste, RO, Brazil (10°45’ S, 62°15’ W and 245 m altitude). The climate of the region is Aw according to the Köppen classification (tropical rainforest climate) with rainy summer (October to May) and dry winter (June to September). The annual average rainfall was 2,000 mm and annual average temperature of 25 °C.

The cuttings were planted in July 2013 and remained to the nursery until October 2013. The experiment was performed with five treatments consisting of five tube volumes (50, 100, 170, 280 and 400 cm³) and a control, using polyethylene bags (11 cm width x 20 cm height) with capacity 770 cm³.

The experimental design was the randomized complete block design with 15 replicates. Each replicate was composed by one of the 15 clones from the C. canephora cv. ‘Conilon - BRS Ouro Preto’. The cultivar stands out in the yield per area (average of 70 bags per hectare of processed coffee), as well as in the characteristics of its plants, tolerance to the main diseases and to the abiotic stresses of the coffee tree occurring in the state of Rondônia, Brazil (ROCHA et al., 2015). The experimental plot consisted of six plants.

The tubes were filled with a mixture of commercial substrates, while the polyethylene bags used fertilizer-enriched soil. The materials used in the filling of containers had their chemical properties determined prior to the addition of fertilizers (Table 1). The analyses were performed by the chemical analysis laboratory of the Embrapa in the municipality of Porto Velho, RO, Brazil.

The mixture used in the study consisted of the commercial substrates Bioplant® and Vivatto Plus® in the 2.5:1 ratio. The Bioplant® substrate shows in its formulation pine bark, coconut fiber, vermiculite, rice husk and nutrients. In contrast, the Vivatto Plus® consists of ground charcoal, pine bark and peat. The Basacote Plus® controlled release fertilizer was added to the substrate mixture in the proportion of 6 kg m⁻³. This fertilizer is composed of 16% N, 8% P₂O₅, 12% K₂O, 2% Mg and 5% S.

The mixture of 210 kg soil, 35 kg sand, 1000 g limestone, 1000 g single superphosphate, 200 g potassium chloride and 80 g FTE-BR12 was used to fill the polyethylene bags (control).

The containers were filled with substrate 20 days prior to planting of cuttings and packed in the nursery, irrigated by micro sprinkler systems, combined with an automated timer programmed to maintain humidity at approximately 90% in the first 30 days after planting of cuttings.

In each container, was inserted a vegetative propagule, formed by orthotropic branch segment (cutting) with 4 cm length according to the recommendations proposed by Ferrão et al. (2007). For standardization of the propagule maturity, only the third node, from the apex to the base, of each orthotropic stem was used.

Fertilization and cultural practices were performed according to the crop needs. From the complete emission of the second pair of definitive leaves, 5 g urea dissolved in 10 dm³ water were applied every 15 days.

The phytosanitary control also occurred every 15 days, alternating the application of systemic fungicide based on tebuconazole prepared at the concentration from 50 cm³ to 20 L water and a protector based on copper sulphate prepared in the ratio from 100 g to 20 dm³ water.
After 98 days of the planting of cuttings, the deltamethrin insecticide was applied to control insects at the concentration from 20 cm$^3$ to 220 dm$^3$ water.

The seedlings remained growing for 130 days, showing four pairs of fully expanded leaves. Afterwards, the seedling were removed from the tube, washed to remove the substrate and taken to the laboratory to determine the vegetative characteristics.

The evaluated properties were root volume (RV) in cm$^3$, determined in graduated beaker by displaced volume difference; number of leaves (NL) and number of nodes (NN), determined by direct counting; stem length (SL) in cm, determined by measuring directly the insertion point of the shoot at the stake to the apical meristem; stem diameter (SD) in mm, determined using a caliper at the base of the orthotropic branch, 3 cm above the insertion point of the shoot at the stake.

The materials were taken to the convection oven at 65 °C until reaching a constant mass in order to obtain the root (RDM), stem (SDM) and leaf (LDM) dry mass in g, determined using an analytical balance with a precision of 0.01 g.

It was also determined the shoot dry mass (SHDM), resulting from the sum of the LDM and SDM; total dry mass (TDM), resulting from the sum of the SHDM and RDM; total leaf area (LA) in cm$^2$, determined through the DDA (Digital Area Determiner) free software (FERREIRA; ROSSI; ANDRIGHETTO, 2008) from digital images and Dickson quality index (DQI), obtained by the formula $DQI = [TDM/((SL/SD)+ (SHDM/RDM))]$ (DICKSON; LEAF; HOSNER, 1960). All characteristics were express by one seedling.

Data were subjected to analysis of variance and, when significant effects were detected, regression analyses were performed ($p<0.05$). Data were also subjected to the Dunnett’s test ($p<0.05$) for comparison of treatments with the control.

### 3 RESULTS AND DISCUSSION

All vegetative characteristics were influenced by the studied tube volumes, with exponential trendlines increasing to the maximum point (Figure 1).

There was increase in the vegetative performance of seedlings with the increased tube volume. The growth of plant, shoot and root system as a function of the container volume corroborate with the results reported for *Toona ciliata* M. Roem. (LISBOA et al., 2012), *Cordia trichotoma* (Vell.) Arráb. ex Steud. and *Jacaranda micranta* Cham. (MALAVASI; MALAVASI, 2006), *C. arabica* (VALLONE et al., 2009), *Hymenaea courbaril* L., *Tabebuia chrysotricha* (Mart. ex DC.) Standl.and *Parapiptadenia rigida* Benth. (FERRAZ; ENGEL, 2011), *Ricinus communis* L. (LIMA et al., 2006) and *Pinus taeda* L. (DOBNER JÚNIOR et al., 2013).

Such increase is resulting of a greater area available for root exploration inside the containers, providing a greater development of the root system, greater availability of water and nutrients and better seedling formation, minimizing stress due to lack of water, which can limit the metabolism, influencing the shoot development of the plant (DOBNER JÚNIOR et al., 2013; FERRAZ; ENGEL,2001; MALAVASI; MALAVASI, 2006; STAPE et al., 2010).

The volumes of 50 and 100 cm$^3$ showed values of stem length (SL), stem diameter (SD), leaf area (LA), leaf dry mass (LDM), stem dry mass (SDM), root dry mass (RDM), shoot dry mass (SHDM), total dry mass (TDM) and Dickson quality index (DQI) similar to the control, while the 170, 280 and 400 cm$^3$ volumes showed values higher than control. For the root volume (RV), only the volumes of 280 and 400 cm$^3$ presented results significantly higher than the control (Table 2).
Different volumes of tubes for clonal...
The values obtained for stem length (SL) and stem diameter (SD) were higher than the presented by Braun et al. (2007) in *C. canephora* seedlings with 140 days of nursery, and by Dardengo et al. (2013), working with different containers and levels of shading in *C. canephora* seedlings with 160 days, 30 days longer than the seedlings propagated in the present experiment.

The SL and SD are important characteristics to evaluate the quality of seedlings. Seedlings of higher stem diameter show greater capacity for emission of new roots (NOV AES et al., 2002), providing resistance to environmental stress conditions, ensuring higher survival rates and initial development after planting in the field (FREITAS et al., 2005).

The treatments with 170, 280 and 400 cm³ showed values of RDM, SHDM and TDM higher than the reported by Berilli et al. (2014), working with different substrates in polyethylene bags. The averages obtained for the DQI were between 0.18 and 0.28. The values are close to the cited by Hount (1990) and Marana, Miglioranza and Fonseca (2008), which recommend DQI values above 0.20 as ideal for seedlings. Gomes et al. (2013) stated that this index is efficient to evaluate the quality and robustness of seedlings, incorporating in the calculation values related to the growth and accumulation of dry matter.

The volume vs. control interaction did not influence the NL and NN, but was significant for LA, in which the tubes 170, 280 and 400 cm³ were superior to the control. It was also possible to observe that this increased LA of seedlings was proportional to the increase in the tube volume (FIGURE 1).

*FIGURE 1* - Stem length (cm) (A), stem diameter (mm) (B), number of leaves (C), number of nodes (D), leaf area (cm²) (g), leaves dry mass (F), stem dry mass (g), root dry mass (g) (H), root volume (cm³) (I), shoot dry mass (J), total dry mass (g) (K), Dickson quality index (L) of *Coffea canephora* seedlings propagated in different tube volumes. All characteristics are express by one seedling.

The increase in LA provides a greater ability to intercept light, thus promoting plant development (PARTELLI et al., 2006a).

The LA values were also higher than the best values obtained by Dardengo et al. (2013). For the tubes 170, 280 and 400 cm$^3$, the LA values were higher than obtained by Lemos et al. (2015) in coffee plants subjected to the application of different concentrations of citric acid and phosphorus in the substrate, demonstrating satisfactory seedling growth in the present experiment.

In short, the study results indicate that higher tube volumes can promote a vigorous and balanced development between shoot and root system. On the other hand, Lemos et al. (2015) emphasized that the substrate represents a high value in the production cost. Thus, how the tube of 280 cm$^3$ showed enough vegetative development of seedlings, the use of larger tubes would not justify.

The container size must be considered too in relation to the time that seedlings will remain in the nursery before the final planting in the field. This is because, even considering that the volumes of 50 and 100 cm$^3$ did not differ from the control, the permanence of seedlings in these containers for a period superior to the studied could promote delayed growth and development of seedlings in the field.

**4 CONCLUSIONS**

The tube volume of 280 cm$^3$ provide the best vegetative performance of seedlings, similarly to volume of 400 cm$^3$, thus, the use of larger tubes would not justify.

Tubes of 50, 100 and 170 cm$^3$ produce seedlings with physiological quality similar to the control until 130 days after staking, but may limit the development of seedlings in a longer period.
